

DEFINITION the central concept underlying all computation is that of the algorithm an algorithm is a step-by-step sequence of instructions for carrying out some task programming can be viewed as the process of designing and implementing algorithms that a computer can carry out. a programmer's job is to: create an algorithm for accomplishing a given objective, then translate the individual steps of the algorithm into a programming language that the computer can understand

ALGORITHM ANALYSIS determining which algorithm is "better" is not always clear cut 2 allows you to perform multiple comparisons simultaneously · it depends upon what features are most important to you the time needed to find the oldest person is if you want to be sure it works, choose the /clearer algorithm if you care about the time or effort required, need to analyze performance which turns out to be the logarithm (base 2) of the involves asking each person's birthday number of people and then comparing it to the birthday written on the page if you double the amount of people, the time needed to find the oldest person increases by a the amount of time to find the oldest person is factor of one more comparison if you double the amount of people, the time needed to find the oldest person will also double

BIG-OH NOTATION

- to represent an algorithm's performance in relation to the size of the problem, computer scientists use
 what is known as Big-Oh notation
 - executing an O(N) algorithm requires time proportional to the size of problem
 - given an O(N) algorithm, doubling the problem size doubles the work
 - executing an O(log N) algorithm requires time proportional to the logarithm of the problem size
 - given an O(log N) algorithm, doubling the problem size adds a constant amount of work
- based on our previous analysis:
 - algorithm 1 is classified as O(N)
 - algorithm 2 is O(log N)

ANOTHER ALGORITHM EXAMPLE

- SEARCHING: a common problem in computer science involves storing and maintaining large amounts of data, and then searching the data for particular values
 - data storage and retrieval are key to many industry applications
 - search algorithms are necessary to storing and retrieving data efficiently
 - e.g., consider searching a large payroll database for a particular record
 - if the computer selected entries at random, there is no assurance that the particular record will be found
 - · even if the record is found, it is likely to take a large amount of time
 - · a systematic approach assures that a given record will be found, and that it will be found more efficiently
- there are two commonly used algorithms for searching a list of items
 - sequential search general purpose, but relatively slow
 - · binary search restricted use, but fast

SEQUENTIAL SEARCH **sequential search is an algorithm that involves examining each list item in sequential order until the desired item is found **sequential search for finding an item in a list 1. start at the beginning of the list 2. for each item in the list i. examine the item - if that item is the one you are seeking, then you are done ii. if it is not the item you are seeking, then go on to the next item in the list 3. If you reach the end of the list and have not found the item, then it was not in the list **sequential search guarantees that you will find the item if it is in the list **but it is not very practical for very large databases **but it is not very practical for ve
